Abstract

Objective: Glucocorticoid (GC) sensitivity is highly variable among individuals and has been associated with susceptibility to develop (auto-)inflammatory disorders. The purpose of the study was to assess GC sensitivity in Behçet’s disease (BD) by studying the distribution of four GC receptor (GR) gene polymorphisms and by measuring in vitro cellular GC sensitivity.

Methods: Healthy controls and patients with BD in three independent cohorts were genotyped for four functional GR gene polymorphisms. To gain insight into functional differences in in vitro GC sensitivity, 19 patients with BD were studied using two bioassays and a whole-cell dexamethasone-binding assay. Finally, mRNA expression levels of GR splice variants (GR-α and GR-β) were measured.

Results: Healthy controls and BD patients in the three separate cohorts had similar distributions of the four GR polymorphisms. The Bcll and 9b minor alleles frequency differed significantly between Caucasians and Mideast and Turkish individuals. At the functional level, a decreased in vitro cellular GC sensitivity was observed. GR number in peripheral blood mononuclear cells was higher in BD compared with controls. The ratio of GR-α/GR-β mRNA expression levels was significantly lower in BD.

Conclusions: Polymorphisms in the GR gene are not associated with susceptibility to BD. However, in vitro cellular GC sensitivity is decreased in BD, possibly mediated by a relative higher expression of the dominant negative GR-β splice variant. This decreased in vitro GC sensitivity might play an as yet unidentified role in the pathophysiology of BD.

Key Words
- Behçet’s syndrome
- single nucleotide polymorphism
- glucocorticoid sensitivity
Behçet’s disease (BD) is an inflammatory disorder characterized by recurrent episodes of orogenital ulcers, uveitis, arthritis, and skin lesions. Less frequent symptoms include gastrointestinal lesions and involvement of the central and peripheral nervous system. The onset of disease is typically in the third or fourth decade of life and equally affects men and women.

BD is common along the ancient Silk Road, which extends from Eastern Asia to the Mediterranean area. The highest prevalence occurs in Turkey (80–420 cases per 100,000), followed by Middle and Far Eastern countries (13.5–20 cases per 100,000). In contrast, the prevalence in Western countries is much lower; ~0.12–5.1 per 100,000 (1, 2, 3).

The etiology of BD is unknown. It is mainly considered a multi-factorial disease and it is associated with the presence of human leukocyte antigen variants, in particular HLA-B51 (3). Variations in several other genes like the tumor necrosis factor, interleukin 10 (IL10), and the nucleotide-binding oligomerization domain containing two (NOD2) genes are also associated with BD (4, 5, 6). Immunohistochemically, BD is characterized by the presence of vasculitis and infiltration of tissue by neutrophils and mononuclear cells (7).

Interestingly, BD also displays some features distinctive of autoimmune processes. First, cellular immunity is disturbed in BD as exemplified by autoreactive T cells-targeting heat shock protein 60 (8). For many autoimmune disorders, autoreactive T cells are a primary culprit in their pathogenesis. Second, several autoantibodies have been described targeting numerous antigens, including CTLA-4 (9) (enhancing T cell proliferation), retinal S-antigen (10), and antikinectin (11), providing evidence for a dysfunctional humoral immune response. In general, BD might be regarded an immune-mediated inflammatory disease.

Glucocorticoids (GC) play a key role in mediating a balanced inflammatory response. GCs exert their effects via interaction with the GC receptor (GR). After binding with its ligand, the GR–GC complex migrates to the nucleus to induce (‘transactivation’) or to suppress (‘transrepression’) expression of target genes. The ultimate biological effects of (endogenous) GC depend on the GC sensitivity of an individual, which is influenced by both genetic and acquired (disease-related) factors. Hence, decreased GC sensitivity could lead to unrestricted immune activation and facilitation of a chronic inflammatory process, a hallmark of many autoimmune disorders.

Indeed, decreased GC sensitivity has been shown to be involved in several autoimmune diseases. For instance, carriers of polymorphisms of the GR gene associated with reduced (i.e. 9β) or increased (i.e. Bcll and N363S) GC sensitivity have increased, respectively, decreased susceptibility to develop rheumatoid arthritis (RA). In addition, carriers of the ER22/23EK allele of the GR gene, which is associated with decreased GC sensitivity, had a more severe disease course (12). At the functional level, van Winsen et al. (13) showed that in patients with multiple sclerosis, higher doses of dexamethasone were required to suppress LPS-induced TNF-α production in peripheral blood mononuclear cells (PBMC) when compared with healthy controls. Also in active RA, PBMCs were less sensitive to dexamethasone in vitro (14). Finally, an increased expression of the GR splice variant GR-β, the dominant negative inhibitor of the biologically active GR-α, is associated with GC resistance in several inflammatory disorders (15, 16, 17, 18, 19, 20).

As decreased GC sensitivity may contribute to immune-mediated inflammatory diseases, we hypothesized that decreased GC sensitivity is involved in the pathophysiology of BD. To test our hypothesis, we genotyped three independent cohorts of patients with BD for the prevalence of four functional GR polymorphisms. Furthermore, in vitro GC sensitivity was assessed by measurement of GR-binding capacity (GR number and affinity) and by two bioassays (21). In these bioassays, dexamethasone-regulated expression of IL2 and GC-induced leucine zipper (GILZ) in PBMC is measured. Transrepressive effects of GC, traditionally considered to be the predominant mechanism regulating anti-inflammatory actions of GC, are represented by the IL2 assay. The GILZ assay embodies all transactivated genes, mediating both anti-inflammatory effects of GC as well as (metabolic) side effects (22, 23). Using these bioassays, a spectrum of GC sensitivity could be demonstrated in healthy individuals (21). Finally, we measured mRNA expression levels of GR-α and GR-β.

**Patients and methods**

**Patients**

To study the prevalence and distribution of the GR polymorphisms, three cohorts with a total of 290 unrelated BD patients were included in the study (56 patients from the Erasmus MC, Rotterdam; 109 patients

from The Jordan Hospital, Amman, Jordan and St John’s Ophthalmic Hospital, Jerusalem, Israel; 39 patients from St Thomas’ Hospital, London, UK, and 86 patients from the University of Cukurova, Adana, Turkey. Of those, 55 were Caucasians, 125 of Middle Eastern (ME) origin or Arab descent, and 110 patients were of Turkish descent.

The control population consisted of 150 Turkish and 75 ME individuals. Caucasian controls (n = 5295–5413, depending on polymorphism) were participants in the Rotterdam Study, a population-based prospective cohort study on determinants of disease and disability in persons, aged 55 years and older, living in Rotterdam, The Netherlands.

To study functional differences in in vitro GC sensitivity in patients with BD, 19 consecutive BD patients from our outpatient clinic were included in the study. Experienced clinical immunologists (JAM vL and PM vH) examined all patients and assessed disease activity using the validated BD current activity form (BDCAF) (24). As a control group, we studied 20 healthy Caucasian laboratory employees. None of the patients or controls used GCs in the last 3 months. All patients described in this study fulfilled the International Study Group criteria for the diagnosis of BD (25).

Assessment of in vitro GC sensitivity

Functional in vitro assays ▶ Recently, two bioassays to determine GC sensitivity were developed in our laboratory (21). In short, peripheral blood was drawn in all patients using Cell Preparation Tubes with sodium heparin (Becton Dickinson, Breda, The Netherlands) allowing isolation of PBMC. Cells were resuspended in RPMI 1640 medium containing l-glutamine supplemented with penicillin (100 U/ml), streptomycin (100 μg/ml), and 10% fetal bovine serum, and precultured overnight in a 48-well plate (Costar, Amsterdam, The Netherlands) at a density of 4.0 × 10⁶/ml. Trypan blue staining revealed the viability of isolated cells to be > 95%. The next day, cells were incubated with increasing doses of dexamethasone (range 0–333 nM) and stimulated with phytohaemagglutinin 10 μg/ml (Sigma–Aldrich). After 4 h in the incubator, total RNA of the cells was collected (total RNA isolation Kit, Roche). cDNA was synthesized using 100 ng RNA and Taqman Reverse Transcription Reagent (N808-0234, Applied Biosystems). For quantitative real-time PCR analysis, the Taqman Technology was applied according to the manufacturer’s instructions. GC-specific transactivation of the GILZ mRNA and transrepression of the IL2 mRNA were measured. Half maximal effective concentration (EC₅₀) was used as a readout for in vitro GC sensitivity. The EC₅₀ values of GILZ and IL2 in PBMC were comparable when different compositions of lymphocytes and monocytes were tested (data not shown). In addition, we measured the affinity and number of GR using a whole cell dexamethasone-binding assay, as described previously (27).
(in duplicate) were lysed and total RNA was extracted immediately (Total RNA isolation Kit, Roche). cDNA was synthesized using 200 ng RNA and Taqman Reverse Transcription Reagent (N808-0234, Applied Biosystems) in a total volume of 50 μl. Gene expression levels of GR-α and GR-β were measured using premanufactured assays (Applied Biosystems, Hs00230818_m1 and Hs00354508_m1 respectively). All results were corrected for the housekeeping gene hypoxanthine phosphoribosyltransferase 1 (HPRT1).

Statistical analysis

To analyze possible associations between GR genotypes and risk of having BD, we calculated odds ratios and 95% confidence intervals for hetero- and homozygous individuals separately (wildtype allele as reference). Given the low number homozygous carriers of the N363S and ER22/23EK minor allele, hetero- and homozygous carriers were analyzed together. Pearson χ²-tests were performed to test for differences in distribution of the polymorphisms between the various ethnic groups. Differences in continuous variables between the cohorts were tested using Mann–Whitney U tests and ANOVA. IL2-EC₅₀ was square-root transformed and number of receptors and Kᵦ were both natural logarithm transformed to normalize the data. All statistical analysis was performed using SPSS for Windows, release 17.0 (SPSS, Chicago, IL, USA) and we considered differences statistically significant if P values were <0.05 (two-sided).

Ethical approval

This study was approved by the medical ethics committee of the Erasmus Medical Center and all subjects signed informed consent.

Results

GR polymorphisms

Healthy controls and BD patients in the three separate cohorts had similar distributions of the four GR polymorphisms (Table 1). Prevalence of the Bcll minor allele was significantly higher in Caucasians compared with both Turkish and ME persons (37.1% in Caucasians vs 21.5 and 21.0% in Turkish and ME persons, respectively, P <0.001). In contrast, the 9b minor allele was less prevalent in Caucasians compared with the Turkish and ME persons (17.2% in Caucasians vs 28.5 and 29.6% in Turkish and ME persons, respectively, P <0.001).

In vitro GC sensitivity

We included 19 BD patients from our outpatient clinic. These patients used a wide spectrum of anti-inflammatory agents, including NSAIDs (n=7, 36.8%), colchicine (n=5, ...
26.3%), hydroxychloroquine (n = 4, 21.1%), TNF-α blockers (n = 2, 10.5%), and pentoxifylline (n = 3, 15.8%). Thalidomide, methotrexate, interferon-α, and octreotide were each used by one patient. Further baseline characteristics and clinical features (present at any time in the disease course) are summarized in Table 2. None of the patients had involvement of the central nervous system.

Patients with BD had higher mean EC50 values in both the IL2 assay and GILZ assay compared with healthy controls (mean IL2 EC50 (95% CI): 10.80 (7.91–14.15) nM in BD vs 3.48 (2.16–5.10) nM in HC, \( P < 0.001 \); mean GILZ EC50 (95% CI): 12.16 (10.91–13.42) nM in BD vs 8.13 (6.69–9.58 nM) in HC, \( P < 0.001 \)) indicating decreased in vitro GC sensitivity in BD (Fig. 1). The maximum induction of GILZ and repression of IL2 did not differ significantly (data not shown). The GR number in PBMC (mean, 95% CI) was higher in BD (10380, 8593–12539 GR/cell) compared with controls (6652, 5719–7738 GR/cell, \( P < 0.001 \)), whereas the mean Kd (95% CI) of the receptor did not differ between patients (8.34, 6.62–10.50 nM) and controls (8.46, 7.37–9.71 nM). Importantly, the EC50 values of GILZ and IL2 and the number of GR did not differ significantly between Caucasian and Turkish and ME patients (Fig. 1). Patients and healthy controls had comparable percentages of monocytes (mean ± S.D.: 18.9 ± 5.5 in BD vs 20.9 ± 5.0 in healthy controls). Ligand affinity of monocytes and lymphocytes did not differ significantly. The number of GRs per cell was about three fold higher in monocytes as compared with lymphocytes (data not shown).

No correlations were found between the BDCAF-score and parameters of in vitro GC sensitivity. Men and women had equal mean levels of IL2-EC50 and GILZ-EC50. Likewise, there were no gender differences at the level of the number of GR or the affinity of the GR.

In 12 BD patients and healthy controls, mRNA expression levels of GR-α and GR-β were measured. BD patients showed a trend toward lower mRNA expression levels of GR-α whereas mRNA expression levels of GR-β tended to be higher. Combined, the GR-α/GR-β ratio was significantly lower in patients (\( P = 0.014 \); Fig. 2).

**Discussion**

The results of our study suggest that decreased GC sensitivity might play a role in the pathophysiology of BD. More specifically, both transactivating and transrepressing pathways of GC action seem to be affected in BD, together with an altered expression of the GR in PBMC. At the transcriptional level, a lower GR-α/GR-β ratio was observed in BD.

We examined the prevalence of four functional GR polymorphisms in three independent cohorts. None of the GR polymorphisms was associated with susceptibility to BD, consistent with two recent genome-wide association studies from Turkey and Japan (5, 28). However, we found significant differences in the prevalence of GR
polymorphisms between the Caucasian and Turkish and ME cohort, which have not been reported before. The Bcll minor allele is associated with increased GC sensitivity (26) and is present at a lower frequency in the Turkish–ME cohort. The Bcll minor allele is also less prevalent in other areas with relatively high prevalence of BD (e.g. China, Korea), as compared with allele frequencies observed in Caucasian populations (29, 30). On the other hand, the 9β minor allele, which is associated with decreased GC sensitivity (26), showed a lower prevalence in the Caucasian population. The clinical relevance of these observations is yet unclear, but they do not directly support the concept of a ‘GC-resistant’ genetic profile contributing to the development of BD as a comparable prevalence of the Bcll and 9β minor alleles was found in the Turkish and ME patients and healthy controls. Future studies should examine whether the different prevalence pattern of GR polymorphisms in the Turkish–ME population is associated with other immune-mediated disorders.

To further explore the role of GC sensitivity in BD, we assessed transactivating and transpressing capacity of GC in vitro by measuring the EC50 values of two representative GC-mediated genes, GILZ (TSC22D3) and IL2. We measured higher EC50 values of both genes in BD, indicating decreased in vitro GC sensitivity compared with healthy controls. In contrast, we found higher numbers of GR per cell, which might reflect a compensatory upregulation of the GR. Importantly, most patients in our study had relatively low BDCF scores, suggesting that the higher EC50 values are not solely influenced by higher levels of pro-inflammatory cytokines, a well-known mechanism of acquired GC resistance (31). Diminished (counterbalancing) cellular effects of GC on the immune system could allow for the development of chronic (auto-)inflammatory processes as in BD. A point of future attention is that in this relatively small group of patients there was considerable variation with respect to the use/not use of disease-modifying drugs. In this setting, it was not possible to analyze the possible effects of these drugs on the outcome of the assays.

In clinical practice, GCs are widely used in BD. However, the only randomized clinical trial studying the effects of GC in BD showed a lack of efficacy of GC treatment. In this study, 3-weekly depots of 40 mg methylprednisolone acetate during 27 weeks in patients with active BD demonstrated no benefit over placebo-treated patients with respect to orogenital ulcers, folliculitis, and arthritis, although lesions with erythema nodosum did improve following GC treatment (32).

Interestingly, in asthma and RA approximately one-third of patients are also GC resistant (33, 34). In addition, a case series reported by Tanaka et al. (35) showed that patients who had ocular manifestations of BD with low in vitro GC sensitivity had a worse clinical course as defined by more frequent relapses of ocular inflammation and higher intraocular pressure. Therefore, the observed decreased in vitro GC sensitivity in BD may not only contribute to an increased understanding of the (etio)pathophysiology of the disease but could also have direct clinical implications. Obviously, it would be of great interest to study whether assessment of in vitro GC sensitivity, as measured by the IL2, GILZ, and whole cell dexamethasone-binding assays, correlates with in vivo response to GC therapy in BD. Insights in the patients response to exogenously administered GC before the start of therapy could then be used to facilitate more individualized GC therapy.

In order to examine possible mechanisms underlying this decreased GC sensitivity in BD, we determined mRNA expression levels of the α and β splice variant of the GR. GR-β is thought to act as a dominant negative inhibitor of the biologically active GR-α by means of competition for co-factors, formation of inactive heterodimers with GR-α, and possibly competition for GRE in vitro (15, 16, 19). High expression of GR-β in vivo has been associated with GC-resistant states in inflammatory bowel disease, asthma, and RA (17, 18, 20, 36, 37). In our cohort, the ratio of GR-α/GR-β was significantly lower in patients with BD and could therefore partially explain the decreased cellular GC sensitivity in BD, although the clinical relevance of the very low expression levels of GR-β are still the subject of debate. Other mechanisms possibly underlying the decreased cellular GC sensitivity in BD may include disturbed nuclear trafficking of the GR via phosphomodulation by kinases and phosphatases, interference with the transcriptional machinery by histone acetyltransferases modulating protein acetylation or transcriptional blocking by altered expression of micro-RNAs.

It must be kept in mind that our data represent relatively small groups, with mixed ethnic background. In this perspective, it is important to note that the Caucasian and Turkish–ME patients with BD were equally distributed with respect to the bioassays, GR assay, and the gene expression levels. Therefore, we assumed that ethnic background is not a major factor determining outcomes of the bioassay, GR assay or gene expression levels, and analyzed Caucasian and Turkish–ME patients together. Also, mRNA levels of GR-α and GR-β do not necessarily represent protein expression levels in our patients. Finally, the interpretation of cross-sectional data is limited with...
respect to dynamic processes as the pathogenesis of BD. Therefore, longitudinal studies evaluating GC sensitivity at various stages of BD, including recent-onset disease, and different levels of disease activity will provide more insight into the importance of GC sensitivity and the development of BD.

In conclusion, polymorphisms of the GR gene are not associated with susceptibility to BD. However, our in vitro data indicate decreased cellular GC sensitivity in BD. This altered GC sensitivity could play an as yet unidentified role in the etiopathophysiology of BD. A decreased GR-γ/GR-β ratio may in part explain this decreased GC sensitivity.
