Abstract

The objective of this study was to investigate whether there is a bidirectional association between testosterone concentrations and insulin resistance, in a prospective population study. A random population sample of 1400 men, aged 30–74, was examined in 2002–2005 in southwestern Sweden and followed up in 2012–2014 ($N=657$). After excluding subjects without information on sex hormones and insulin resistance, 1282 men were included in the baseline study. Fasting measurements of plasma glucose, insulin and hormones were performed. Insulin resistance was defined using HOMA-Ir. Mean age at baseline was 47.3 ± 11.4 years. From the follow-up survey 546 men were included, mean age 57.7 ± 11.6 years. Low concentrations of total testosterone at baseline were significantly associated with high logHOMA-Ir at follow-up in a multivariable model including age, waist–hip ratio, physical activity, alcohol intake, smoking, LDL, CRP, hypertension, diabetes and logHOMA-Ir at baseline as covariates ($\beta = -0.096$, $P=0.006$). Similar results were observed for bioavailable testosterone. Men within the lowest quartile of total testosterone at baseline had significantly higher logHOMA-Ir at follow-up than other quartiles (Q1 vs Q2 $P=0.008$, Q1 vs Q3 $P=0.001$, Q1 vs Q4 $P=0.052$). Multivariable analysis of the impact of insulin resistance at baseline on testosterone levels at follow-up revealed no significant associations regarding testosterone concentrations ($\beta = -0.003$, $P=0.928$) or bioavailable testosterone ($\beta = -0.006$, $P=0.873$), when adjusting for baseline concentrations of total testosterone, age, waist–hip-ratio, LDL, CRP, physical activity, alcohol intake, smoking, hypertension and diabetes. Low testosterone concentrations at baseline predicted higher insulin resistance at follow-up, but high insulin resistance at baseline could not predict low testosterone at follow-up.

Introduction

Testosterone plays a key role in the regulation of glucose and lipid metabolism in men (1) and women (2) although in different manners. Low concentrations of testosterone in men are associated with obesity (3), the metabolic syndrome (4) and hypertension (5). However, it is not fully understood whether there is a causal association or if low testosterone is a surrogate biomarker of poor health (6).

Increased visceral fat leads to raised secretion of proinflammatory cytokines, leptin, estradiol and insulin. These substances may inhibit the activity of the hypothalamic–pituitary gonadal axis at multiple levels, thus lowering the concentrations of testosterone (7). There is also evidence that obesity increases aromatase activity in the fat tissue, converting testosterone to estradiol (8).

which may play an important role in the regulation of body fat as well (9), and further inhibit testosterone production by negative feedback on the hypothalamic–pituitary–gonadal axis (10). On the other hand, low testosterone levels increase the accumulation of visceral body fat, which increases insulin resistance. This is illustrated by the fact that body fat increases in men with prostate cancer undergoing treatment resulting in hypogonadism (11). Furthermore, there is evidence that testosterone could increase insulin sensitivity by decreasing the levels of cytokines (TNF α and IL6), which are believed to increase insulin resistance (12, 13). Therefore, it has been suggested that there is a bidirectional relationship between low levels of testosterone and abdominal obesity in men (7, 14, 15, 16), but there is a lack of longitudinal studies investigating this bidirectional relationship.

There are several prospective studies that support the hypothesis that low testosterone levels in men increase the risk for developing diabetes and the metabolic syndrome. Both the NHANES III-study and the Massachusetts Male aging study found an increased risk of type 2 diabetes and the metabolic syndrome in men with low concentrations of testosterone (17, 18, 19). This association has also been found in older men in the Rancho Bernardo cohort (20) and in a Finnish cohort of middle-aged men (21). Another study investigated levels of sex hormones and the risk of developing type 2 diabetes in a prospective design with 9-year follow-up (22). The study showed that higher levels of testosterone predicted a lower risk of type 2 diabetes in elderly men. Furthermore, in a recent study of over 2000 community-dwelling middle-aged to elderly men, and with a 5-year follow-up, similar results were found – low total testosterone concentrations predicted the development of type 2 diabetes (23). However, another prospective study including over 5000 men and with a follow-up of 29 years, identified that low testosterone and low levels of SHBG, but not luteinizing hormone (LH), were associated with a higher risk of developing type 2 diabetes, indicating that low testosterone is a risk marker rather than a risk factor for type 2 diabetes, since hypogonadism per se did not seem to be associated with an elevated risk of type 2 diabetes (24). Testosterone has also been shown to decrease insulin resistance, total cholesterol and LDL cholesterol, as shown in one of the largest RCTs investigating the effect of testosterone replacement on insulin resistance in men with type 2 diabetes or metabolic syndrome (25).

While the evidence that low testosterone levels are associated with the development of insulin-resistant states and type 2 diabetes is abundant, less is known

about whether insulin resistance influences the decrease in testosterone levels. A bidirectional association has been suggested but the evidence in support of this assumption is weak. Thus, the aim of this study was to investigate whether there is a bidirectional association between testosterone and insulin resistance.

Subjects and methods

Study population

This is a longitudinal observational study of the Vara-Skövde cohort. Between 2002 and 2005 a sample of 1400 men, aged 30–74, living in southwestern Sweden were randomly selected for a cohort study with the goal to detect risk factors for cardiovascular disease at an early stage (26). During the follow-up visit, a representative sample of the participants was consecutively summoned in 2012–2014, and 657 men completed the study protocol accordingly. Among the invited individuals, 217 men declined participation (details shown in Fig. 1). A non-response analysis showed that the non-responders were significantly older (mean difference 2.0 ± 0.4 years, $P < 0.001$), and proportionately more of them were smokers, compared to responders (21.1% vs 14.1%, $P < 0.001$), but no other significant differences were found between the groups.

Physical examination

Specially trained nurses assessed study participants, measuring body weight, height, waist circumference and blood pressure in supine and sitting position at follow-up, supine and standing at baseline. Waist–hip ratio was calculated. Validated questionnaires were used to obtain information on lifestyle including smoking, alcohol intake and leisure time physical activity.

Laboratory analyses

Fasting venous blood samples were drawn in the morning and after an oral glucose tolerance test. Serum concentrations of testosterone and sex hormone-binding globulin were obtained using radioimmunoassay at baseline and at follow-up (27). All blood samples were immediately frozen at -82°C . Diabetes and hypertension were defined based on WHO and JNC8 recommendations, respectively, according to information obtained from medical history and clinical assessment (28, 29). Concentrations of insulin and glucose at fasting

Figure 1

Flow chart showing the study population.

were measured, and HOMA-Ir (homeostatic model assessment of insulin resistance) was calculated by using the formula: $\text{fasting insulin} \times \text{fasting glucose} / 22.5$, in subjects without insulin therapy (30). Bioavailable testosterone (which is the sum of free testosterone and the albumin bound testosterone) was calculated using the formula according to Vermeulen *et al.* (31). Due to changes in insulin measurement methodology (from Roche Cobas to DxI Beckman) in 2011, the insulin values at follow-up were about 35% higher than at baseline. The insulin values therefore had to be re-calculated with the following formula: $\text{New method} = 1.3544 \times \text{old method} + 0.3237$. The correlation between methods was $r^2 = 0.9974$. The correlation between methods was investigated within the laboratory which provided the

formula for the re-calculation. The method used for analyzing testosterone was radioimmunoassay (RIA) at both visits. However, during the follow-up time, there was a shift on the reagent used in Sweden and Europe from Access Testosterone assay Beckman-Coulter to Elecsys Testosterone II Assay from Roche Diagnostics. The new method gives higher values in total testosterone concentrations compared to the old one used at baseline. We did not have access to an algorithm to adjust for the new method. Due to these changes in testosterone measurement method, analyses investigating change of testosterone over time were not possible. However, strong correlation between the baseline levels of testosterone and follow-up levels was observed (Pearson correlation 0.617, $P < 0.001$).

At baseline, the analyses of testosterone were successful in 97.4% of the participants (1364/1400 individuals). The measurements of insulin were successful in 99.5% (1393/1400 individuals).

Statistical analyses

Descriptive statistics were used to describe the characteristics of the study population at baseline and follow-up. Due to skewness in HOMA-Ir, this variable was log-transformed. Theoretical models adjusting for possible confounding factors were built. Linear regression cross-sectional analyses were conducted to investigate the association between sex hormones and insulin resistance at baseline and at follow-up, with logHOMA-Ir as the dependent variable and sex hormone (either total testosterone or bioavailable testosterone) as explanatory variable. The analyses were adjusted for potential confounders, including age, smoking, physical activity, alcohol intake, WHR, LDL, CRP, hypertension and type 2 diabetes mellitus. The longitudinal analyses were conducted using logHOMA-Ir and sex hormones, respectively, at follow-up as dependent variables and sex hormones and logHOMA-Ir, respectively, at baseline as the explanatory variables. The analyses were adjusted for the same confounders as in the cross-sectional analyses but included also adjustment for the baseline measurement of the outcome variable. General linear models were also performed to compare the variance of log-transformed HOMA-Ir in different quartiles of testosterone. The comparison was pairwise and the lowest quartile was the reference. To investigate age-related differences in the association between bioavailable testosterone and insulin resistance, stratified analyses were conducted for subjects above and below 50 years of age at baseline. Analyses were conducted using IBM SPSS Statistics, version 24.

Ethics

The Regional Ethical Review Board in Gothenburg, Sweden, approved the study (D-nr 036-12 and 199-01) and all participants gave their written consent to participation.

Results

The mean follow-up time was 9.7 ± 1.4 years. After excluding subjects with no information in sex hormones and insulin resistance, 1282 men were included in the baseline study. All participants with valid values in all

variables used as covariates in the model were included (baseline $N=1282$, follow-up $N=546$, longitudinal analysis $N=578$) (Fig. 1). The mean age at baseline was 47.3 years (s.d. 11.4), and at follow-up the mean age was 57.7 years (s.d. 11.6). Further characteristics of the study population at baseline and follow-up are presented in Table 1. In the cross-sectional analyses, concentrations of total serum testosterone were strongly associated with insulin resistance, both at baseline ($\beta=-0.302$, $P<0.001$, $N=1282$), and at follow-up ($\beta=-0.325$, $P<0.001$, $N=546$) (Table 2) when adjusted for age. The association was still significant after adjustments for additional relevant confounding factors; waist-hip-ratio, smoking, leisure time physical activity, alcohol intake, LDL, CRP, diabetes status and hypertension (baseline $\beta=-0.140$, $P<0.001$, $N=1282$, follow-up $\beta=-0.181$, $P<0.001$, $N=546$). The association was significant also for bioavailable testosterone at baseline when adjusted for age, physical activity and smoking ($\beta=-0.109$, $P<0.001$, $N=1282$), but not significant when adjusted for waist-hip ratio.

No significant differences in these associations were observed when we stratified for age above and under 50 (excluding adjustment for age) (age <50 $\beta=-0.020$, $P<0.502$; age ≥ 50 $\beta=-0.005$, $P=0.914$). However, at follow-up, the cross-sectional analysis (not stratified for age) showed a strong and significant inverse association between bioavailable testosterone concentrations and HOMA-Ir even in the fully adjusted model ($\beta=-0.114$, $P=0.004$, $N=546$) (Table 2).

In the longitudinal analysis, low concentrations of total testosterone at baseline were associated with higher levels of logHOMA-Ir at the follow-up in a multivariable model including age, waist-hip-ratio, baseline logHOMA-Ir, smoking, physical activity, alcohol intake, LDL, CRP, diabetes and hypertension as covariates ($\beta=-0.096$, $P=0.006$, $N=578$). The longitudinal association was also significant for bioavailable testosterone ($\beta=-0.079$, $P=0.035$) (Table 3).

Men within the lowest quartile of total testosterone at baseline had significantly higher HOMA-Ir at follow-up than men within the second and third quartiles. (Mean HOMA-Ir Q1: 2.23, Q2: 1.84, Q3: 1.71, Q4: 1.93. Q1 vs Q2 $\Delta\text{mean}=P=0.008$, Q1 vs Q3 $\Delta\text{mean}=P=0.001$) whereas the difference was borderline significant between first and fourth quartile (Q1 vs Q4 $\Delta\text{mean}=P=0.052$), in the fully adjusted model. No significant differences were observed between quartiles 2, 3 and 4 in this regard (Fig. 2).

In the longitudinal analyses investigating the association of insulin resistance at baseline and total or bioavailable testosterone concentrations at follow-up,

Table 1 Characteristics of the study population.

	Baseline (N=1282)	Follow-up (N=546)
Age (years)	47.3 ± 11.4	57.7 ± 11.6
BMI (kg/m ²)	26.8 ± 3.5	27.4 ± 3.6
Waist-hip-ratio	0.94 ± 0.06	0.97 ± 0.06
Systolic blood pressure (mmHg)	124 ± 16	126 ± 13
Diastolic blood pressure (mmHg)	72 ± 10	73 ± 9
Fasting insulin (μU/mL)	6.55 ± 4.8	7.24 ± 4.88
Fasting glucose (mmol/L)	5.5 ± 0.85	5.8 ± 0.9
HOMA-Ir	1.7 ± 1.53	1.9 ± 1.5
Serum testosterone (nmol/L)	14.3 ± 4.3	16.0 ± 5.7
Current smoker N (%)	181 (14.1)	52 (9.5)
Hypertension N (%)	177 (13.8)	79 (14.5)
Diabetes mellitus N (%)	56 (4.4)	34 (6.2)
Level of leisure time physical activity N (%)		
Sedentary	95 (7.4)	62 (11.4)
Low level of physical activity	677 (52.8)	287 (52.6)
Moderate level of physical activity	457 (35.6)	163 (29.9)
Strenuous physical activity	53 (4.1)	34 (6.2)
Sex hormone-binding globuline (nmol/L)	32.3 ± 13.3	46.1 ± 19.6

Note that the method of measuring serum testosterone changed during the survey time, resulting in higher values at follow-up (described in detail in the 'Methods' section).

a crude significant association was found for total testosterone ($\beta = -0.164$, $P < 0.001$) and bioavailable testosterone ($\beta = -0.089$, $P = 0.032$). However, the significance disappeared after adjustment for baseline testosterone/bioavailable testosterone. When stepwise adjustments were made, no significant associations were found in any model in the multivariable analysis ($\beta = -0.034$, $P = 0.309$) (Table 4).

Discussion

In this prospective cohort study, we aimed to investigate the possible bidirectional relationship between

testosterone and insulin resistance by analyzing if a low level of testosterone could predict the development of insulin resistance and vice versa. Our results revealed a significant longitudinal association between lower levels of total testosterone and bioavailable testosterone, respectively, and the development of insulin resistance, which remained significant even after adjustment for possible confounding factors, including waist-hip ratio. This indicates that testosterone itself might have an important and independent effect on the development of insulin resistance over time. However, in this study, the level of insulin resistance at baseline could not predict the decrease in testosterone or bioavailable testosterone level at follow-up. Furthermore, we observed a strong inverse

association between concentrations of testosterone and insulin resistance in the cross-sectional analyses at baseline and follow-up.

Although insulin resistance is driven by obesity, there is evidence that suggests that testosterone modulates the expression of the glucose transporter Glut4 and the insulin receptor in muscle and adipose tissue, thereby improving glucose metabolism (32, 33, 34). The presence of this pathway indicates an effect of testosterone on insulin resistance that is independent from body composition. Furthermore, there is evidence that testosterone withdrawal during 2 weeks in men with idiopathic hypogonadotropic hypogonadism decreases insulin sensitivity and raises HOMA-Ir without changing BMI or leptin levels (35), suggesting an effect of testosterone on insulin resistance not dependent on change in body weight.

However, in a review from 2011 (7), the association between testosterone and insulin resistance seemed to disappear when adjustments for body composition were added to the models. This tendency can also be seen in our study, where the correlations weakened both in the cross-sectional and in the longitudinal studies when adjustments for waist-hip ratio were added to the linear regression models. This connection between body composition and low testosterone can be explained by different mechanisms. There is evidence that testosterone affects the differentiation of the pluripotent stem cells into the myogenic lineage and inhibits their differentiation into adipocytes (36), thereby influencing the body composition and decreasing insulin resistance. These experimental studies are also supported by randomized controlled studies that show significant beneficial changes in the body composition and insulin resistance in individuals treated with testosterone (37, 38).

A reverse causality between testosterone and insulin resistance has been suggested, as in the prospective study by Laaksonen *et al.* (39). The authors of that study paper did not report an association between insulin resistance and testosterone concentrations, but showed that the metabolic syndrome predicts low testosterone in men in an 11-year follow-up. Moreover, in the same study, the insulin levels at baseline did not predict change in testosterone levels. These results are in line with our findings, suggesting that body composition but not insulin resistance is associated in a bidirectional manner with testosterone levels. The impact of body composition on testosterone is further supported by observations in

Figure 2

Quartiles of serum testosterone in follow-up survey. Men with the lowest testosterone concentration at baseline (Q1) had the highest HOMA-Ir at follow-up. Model adjusted for age, waist-hip ratio and HOMA-Ir at baseline.

individuals undergoing gastric bypass surgery where testosterone levels increased significantly following the dramatic weight loss (40, 41). In accordance with these observations, it has also been shown that weight gain or diabetes type 2 drive the decline in testosterone levels over time (42, 43). There are models explaining the impact of body composition on testosterone concentrations, as stated in the hypogonadal-obesity-adipocytokine hypothesis (8, 9, 10, 44). This shows that aromatase activity in adipose tissue converts testosterone to estradiol, which in turn inhibits the hypothalamic-pituitary-gonadal axis, leading to decreased testosterone levels. Leptin and adipocytokines, such as TNF α and IL6, produced in the fat tissue further inhibit the hypothalamic-pituitary-gonadal axis. In addition, leptin also has a negative effect on the Leydig cells, by inhibiting the stimulation of gonadotropin, leading to even further decreased testosterone level. However, even though obesity is associated with higher inflammatory activity, inflammation measured as CRP did not influence the association between testosterone and insulin resistance in our study. Although the evidence is strong that body composition influences testosterone concentrations and insulin resistance, there is also evidence that testosterone has a short-acting effect on insulin resistance, which cannot be explained by change in body weight or body composition, as discussed above (35). However, most of the associations seen in observational studies seem to be explainable by the body composition. Our findings also support the lack of an independent effect of insulin resistance on testosterone levels, as no significant association between insulin resistance at baseline and testosterone levels in follow-up were found. The suggested bidirectional relationship was thus not confirmed. This could be due to the existence of differences that

were too small to be detectable with the use of this method or due to small sample size and long follow-up time. However, even though there may be a bidirectional association, the direction where insulin resistance decreases testosterone levels is much weaker than in the other direction.

In our cross-sectional analyses, there was a strong association between both total testosterone and bioavailable testosterone and insulin resistance at baseline and at follow-up. These results are consistent with other cross-sectional studies (45, 46, 47). However, in the analyses of the bioavailable testosterone, the significance was lost at baseline after adjustments for confounding. There are several possible explanations for the differences in these associations. First, the participants in the study were of different ages at these timepoints, suggesting that the testosterone level is more important for insulin resistance in elderly men. The loss of significance when adjusting for waist-hip ratio indicates that body composition, and visceral obesity in particular, might have a stronger impact on the insulin resistance progress in younger individuals. However, when age-stratified analyses were conducted for subjects above and below 50 years of age at baseline, similar results were obtained in the two groups; significance was lost when waist-hip ratio was added to the adjustment model. This does not support the existence of age differences in these associations. However, there seems to be a non-linear association between testosterone at baseline and HOMA-Ir at follow-up (Fig. 2). In fact, only the lowest quartile differed significantly from the other quartiles, suggesting a threshold effect. In the follow-up survey, more participants may have reached below that threshold, due to higher age and higher prevalence of abdominal obesity, thus showing a stronger and significant association.

Second, different methods of measuring testosterone were used in the baseline survey and in the follow-up, as discussed below. As the method was more precise at follow-up, the associations might be stronger and still significant after adjustments for possible confounding.

Strengths and limitations

The strength of this study is its longitudinal design with high participation rates at both baseline and follow-up visits. Moreover, the large sample size and the systematic characterization of the study population along with the long follow-up time are obvious strengths in this study. The extensive information on the participants enabled us to account for various covariates in the analyses. Due to the size of the study, these results should be valid in other male Caucasian populations.

Some limitations should be mentioned, however. First, the methods of analysing insulin and serum testosterone changed during the observation period, and, therefore, it was not possible to study the change of testosterone or HOMA-Ir over time. Such change in the analyses of the variables is a limitation of the study and may affect the results to some extent due to lower precision and power, which could result in a type 2 error. However, the laboratory did internal validity testing and found high correlation between the new and old method. Thus, these measurements of insulin should be considered comparable, even though we did not do any analyses including change or delta value.

Regarding testosterone it was not possible to compare the levels and to estimate the changes due to the change in the method. Therefore, we were not able to analyse factors that influence the change in testosterone. However, the information about testosterone at baseline permitted adjustments and thus, an estimation of the correlation between insulin at baseline and testosterone at follow-up.

Second, measurements of testosterone were made with radioimmunoassay, which is considered less reliable than mass spectrometry. However, this is particularly true for low concentrations, such as in women or children, and less problematic in healthy adult men with higher concentrations. The radioimmunoassays used showed an acceptable correlation with mass spectrometry values (48, 49). Also, radioimmunoassay is generally used in clinical practice. Due to less reliability when using radioimmunoassay, there is a risk of lower precision in the analyses. However, even with this lower precision we observed a strong association, probably owing to the large size of the cohort. Regarding the measurements

of insulin, we only had one fasting value, taken at the same time in all participants. Since insulin is a pulsatile hormone, it would have been an advantage to calculate the mean value from repeated measurements in order to reduce the risk of type 2 error in the analyses due to lower precision. However this was not possible due to the large sample size, and furthermore, when calculating HOMA-Ir, a single measurement has been considered an acceptable compromise, that obtains similar results in large sample sizes (50). We chose to adjust for waist-hip-ratio to see whether the association between testosterone and insulin resistance was independent of body composition. This might have caused a type 2 error, especially in the cross-sectional analyses at baseline because of collinearity. However, one of the questions we wanted to investigate was whether testosterone influenced insulin resistance through other pathways than the body composition. Thus, we chose to adjust the analyses even for waist-hip-ratio.

Despite the mentioned limitations, there was a consistency in the results, both in the cross-sectional and the longitudinal analyses.

Conclusion

We observed a robust association between low testosterone concentrations and insulin resistance, both cross-sectionally and longitudinally, but this relationship was not bidirectional. While low concentrations of testosterone independently predicted the increase in insulin resistance, no significant impact of insulin resistance on testosterone concentrations was observed during the follow-up time. Further studies including sex hormone-binding globulin and estradiol may provide more insight into the role of sex hormones on the deterioration of insulin resistance.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.
