Abstract

Background/objective: The number of long-term survivors of childhood acute leukemia (AL) is substantially growing. These patients are at high risk for metabolic syndrome (MS), especially those who received total body irradiation (TBI). The consequences of children's irradiation on adipose tissue (AT) development in adulthood are currently unknown.

The objective of this study is to assess the impact of TBI on AT of childhood AL survivors.

Design: We compared the morphological and functional characteristics of AT among survivors of childhood AL who developed MS and received ($n = 12$) or not received ($n = 12$) TBI.

Subjects/methods: Body fat distribution and ectopic fat stores (abdominal visceral and liver fat) were evaluated by DEXA, MRI and ¹H-spectroscopy. Functional characteristics of subcutaneous AT were investigated by studying gene expression and pre-adipocyte differentiation in culture.

Results: Patients who have received TBI exhibited a lower BMI (minus 5 kg/m²) and a lower waist circumference (minus 14 cm), especially irradiated women. Despite the lower quantity of intra-abdominal AT, irradiated patient displayed a nearly two-fold greater content of liver fat when compared to non-irradiated patient (17 vs 9%, $P = 0.008$). These lipodystrophic-like features are supplemented by molecular abnormalities in subcutaneous AT of irradiated patients: decrease of gene expression of *SREBP1* (minus 39%, $P = 0.01$) and *CIDEA* (minus 36%, $P = 0.004$) and a clear alteration of pre-adipocyte differentiation.

Conclusions: These results strongly support the direct effect of irradiation on AT, especially in women, leading to specific nonalcoholic fatty liver disease, despite lower BMI. A long-term appropriate follow-up is necessary for these patients.

Introduction

Advances in the treatment strategies and supportive care for childhood acute leukemia (AL) have resulted in marked improvements in survival, which now exceeds 80% for lymphoblastic and 60% for myeloid AL (1). However, long-term survivors of childhood AL are at increased risk of later in life complications (2, 3); cardiovascular disease (CVD) is a leading cause of mortality for these patients (2). In a cohort of 10,397 survivors of childhood cancer, the relative risk of having coronary artery disease was 10.4 times higher than for their siblings (2). Metabolic syndrome (MS), a major risk factor for premature CVD and type-2 diabetes mellitus (4), is a common complication in this population (5, 6). We have already shown the high prevalence of MS in young adults surviving AL in the LEA cohort ('Leucémie de l'Enfant et de l'Adolescent'): i.e., 9.2% at a mean age of 21 years (6).

Various factors contribute to metabolic abnormalities after AL treatment: growth hormone deficiency (7), chronic inflammation (8), nutritional deficiencies, gut microbiome, endothelial dysfunction (9) and irradiation (6, 10, 11, 12). Several studies have demonstrated that total body irradiation (TBI), given as a conditioning regimen before hematopoietic stem-cell transplantation, represents a major risk factor for developing MS and CVD (10, 11, 12, 13, 14, 15).

In the LEA cohort, MS was found in 18.9% of young adults (mean age 21 years) who had received TBI during childhood (6). Interestingly, even among survivors with MS, patients who received TBI for AL are leaner than those who did not (16). We have recently shown in a cohort of 1025 leukemia survivors that irradiated patients had a particular profile of MS with significantly more pronounced insulin resistance parameters (higher triglycerides, higher plasma glucose levels and lower HDL-C levels) despite lower BMIs and lower waist circumferences when compared to controls (15).

MS is the clinico-biological expression of an insulin-resistant state. Over the years, accumulating evidence has revealed that insulin resistance is the consequence of a deficit in the capacity of subcutaneous fat to store excess energy, resulting in increased accumulation of fat in undesired sites, a phenomenon that has been described as ectopic fat deposition (17). The role of this 'limited subcutaneous AT expandability' is consistent with the severe insulin-resistant state found in patients with lipodystrophic conditions (18). Given the high prevalence of MS, and despite a lower body weight among survivors who received TBI, we hypothesized that exposure to radiation leads to abnormal

fat storage with ectopic fat deposition development deposition and insulin resistance. Previous work by Cousin *et al.* reported that irradiation alters the proliferation and differentiation capacity of adipocyte precursor cells in mice (19). However, the effects of radiation exposure on human AT are unknown. No study to date had the opportunity to explore the AT functionality on AT biopsy in these young leukemia survivors.

To assess the impact of TBI on AT, we compared the morphological and functional characteristics of AT between childhood AL survivors with MS and who had received, or had not received TBI treatment.

Materials and methods

Patients

All the patients described here were included in the LEA program, a historical multicenter and prospective cohort established in 2003 to evaluate the long-term health condition, quality of life and socioeconomic status of survivors of childhood leukemia (3, 20). During the LEA follow-up, medical check-ups were repeated biannually until the age of 20 years and every 4 years thereafter. Since 2007, MS, defined, according to the NCEP-ATPIII criteria (4), was systematically searched for in all adults. For this study, the clinical data and treatments related to AL were obtained by reviewing each patient's medical records. The following inclusion criteria were used: patients were (i) included in the LEA cohort, (ii) aged >18 years, (iii) in follow-up care in the French 'PACA-Corse' area, (iv) diagnosed with MS during the LEA follow-up and (v) had provided written informed consent for participation in this study. All patients were included between May and September 2015. The French National Program for Clinical Research and the French National Cancer Institute approved the LEA program. This study obtained ANSM agreement on February 20th, 2015 and approval from CPP SUD MEDITERRANEE V on April 8th, 2015 (201S-A00170-49). The National Clinical Trial number is 02696304.

Clinical and biological parameters

The following anthropometric data were collected: body weight, height, BMI, waist- and hip circumference (measured by the same physician). The habitus, personal or family history of CVD were equally collected. Dietary intake was evaluated by a dietician using Bilnut 7.5 Windows software. Physical activity was assessed by the specific

questionnaire: 'Global Physical Activity Questionnaire' (21). Indirect calorimetry (Quark PFT ergo, COSMED, Italy) was done to estimate the resting metabolic rate.

Patients underwent blood analysis after overnight fasting that included a lipid profile, fasting plasma glucose, liver-enzyme levels, plasma adipokines and apolipoproteins. Total plasma apoC-III and apoC-II levels were determined using an immuno-turbidimetric assay (Kamiya Biomedical Company, Seattle, WA, USA). A specific ELISA was used to measure serum levels of adiponectin (Quantikine Human Adiponectin, R&D Systems) and leptin (Active Human Leptin DSL Systems). The insulin resistance homeostasis model (HOMA-IR) was calculated as: fasting plasma glucose (mmol/L) × fasting plasma insulin (mIU/L)/22.5.

Body composition and AT distribution

Dual X-ray absorptiometry (DEXA)

Body composition was assessed using the gold-standard dual-energy X-ray absorptiometry (Lunar iDXA, GE Healthcare).

Magnetic resonance imaging

Abdominal MRI (DIXON technique, 3T-MRI, Siemens VERIO, slices acquisition centered at L4–L5) was conducted to analyze the distribution of abdominal AT, that is, superficial subcutaneous abdominal AT (sSAT), deep subcutaneous abdominal AT (dSAT), or visceral abdominal AT (VAT), with high replicability (22) (Supplementary material A, see section on [supplementary data](#) given at the end of this article). MRI was conducted at the Center for Magnetic Resonance in Biology and Medicine (CEMEREM).

Liver fat content assessment

Proton magnetic resonance spectroscopy (¹H-MRS) was used to quantify ectopic fat deposition in the liver (23, 24). Patients were scanned in a head first supine position, using 3T MRI-scanner (Siemens VERIO). A single-voxel proton spectroscopy sequence (PRESS; repetition time=1000 ms, echo time=35 ms, number of excitations=16, and bandwidth of 2000 Hz) was used to determine the molecular content of lipids and water. A spectroscopic voxel was positioned in three different orientations (axial, coronal and sagittal). Minimal rectangular voxel dimensions were 20 × 15 × 15 mm³. All acquisitions were performed during breath holding. Due to the heterogeneity of the ectopic fat content in liver, the hepatic triglyceride content was

assessed in three different locations (left and right liver lobes and the hepatic dome) (25). Two single scan spectra (calculation of water saturation) and two 16-scan spectra were acquired. We observed in each tissue the water spectrum resonance at 4.7 ppm and the lipid resonance (CH₂ of triglycerides (TG)) at 1.3 ppm. Spectra analyses were performed using AMARES (MRUI package) under an Interactive Data Language environment. The liver TG content was expressed as a relative percentage of water signal (% TG = amplitude of TG peak in 16 scans spectrum / amplitude of water peak in single scan spectrum × 100). Using results of the three different areas in liver, we calculated the mean hepatic TG content.

Abdominal subcutaneous AT biopsy

A needle aspiration of abdominal sSAT was performed under local anesthesia. AT samples (200–1000 mg) were obtained and washed in physiological saline. A portion of each biopsy was placed immediately in liquid nitrogen and stored at −80°C until analysis. Another portion was placed in phosphate-buffered saline (PBS) for flow cytometry and cell culture.

Sample preparation and real-time PCR

Total RNA was extracted by needle aspiration from sSAT or from culture using the RNeasy Lipid Mini kit (Qiagen), according to the manufacturer's recommendations. RNA concentration and quality was confirmed using nanodrop (Nd-100, Nanodrop Technologies). cDNA was synthesized from 500 ng of total RNA. Real-time quantitative PCR assays were performed with Sybr green mixes using a thermocycler stratagem Mx3005. We used 18S rRNA as a normalization control. Gene expression changes were evaluated using the LIVAK method (26). Primer designs can be provided on request. For the differentiation markers in culture, real-time PCR assays were run on a StepOne detection system (Life Technologies/Applied Biosystem), and relative gene expression was calculated using the delta-cycle threshold method and normalized to PUM expression.

Flow cytometry

Samples of sSAT were stored in PBS at room temperature and sent to the STROMALab institute in Toulouse on the same day. Stroma-vascular fraction and mature adipocytes were separated as previously described (27). Stroma-vascular fraction cells were incubated with PBS

supplemented with FcR Block reagent (MiltenyiBiotec). Staining was performed by incubating cells for 30 min at 4°C with conjugated primary antibodies or an appropriate immunoglobulin G isotype control (BD Biosciences). DAPI was used for the viability control. Cells were analyzed on a FACS Canto II flow cytometer (BD Biosciences). Data acquisition was performed with FACS Diva software and analysis was performed with Kaluza software (Beckman-Coulter). Pre-adipocyte cells were characterized as CD34⁺/CD45⁻/CD31⁻.

Pre-adipocyte culture

The stroma-vascular fraction was isolated from human sSAT obtained from 14 samples, as previously described (27, 28). Briefly, the stroma-vascular fraction was formed by plating overnight in DMEM medium supplemented with 10% newborn calf serum, 250 µg/mL amphotericin, 5 µg/mL streptomycin and 5 U/mL penicillin. After 24 h, the cultures were washed extensively using PBS to remove residual non-adherent cells. Cells were incubated at 37°C under 5% CO₂, and the medium was changed twice weekly. Cultures were pursued until cells reached 75% confluence. Adipose differentiation was then induced by adding dexamethasone (1 µM), indomethacin (60 µM), isobutyl-methyl xanthine (IBMX, 450 µM), insulin (5 µg/mL) and rosiglitazone (2 µM) for 3 days. The medium was then replaced with the same supplementation medium without IBMX for four additional days. Adipogenic differentiation was evaluated by quantification of the expression of differentiation markers. Adipocytes were quantified by counting the number of lipid-loaded cells under the microscope (Nikon, TE2000S) in randomized sections of the culture plates.

Statistical analysis

All statistical analyses were performed using Prism software (GraphPad software 6.0). Values are expressed as mean ± standard deviation (s.d.). The Gaussian distribution of all parameters was tested and parametric (unpaired Student's *t*-test) or nonparametric tests (Mann-Whitney test) were selected, as appropriate. Fisher's exact test was used for non-continuous variables. Statistical significance was defined as *P* < 0.05.

Results

Patients characteristics

Among the 409 adult patients included in the LEA cohort and followed in the French area 'PACA-Corse', 337 patients

were screened for MS. Of these 337 patients, 37 had been diagnosed with MS during the LEA follow-up and fulfilled all the inclusion criteria, of which 24 agreed to participate in the study (flow chart in Supplementary Table A). Twelve patients who had received TBI as a conditioning regimen before hematopoietic stem-cell transplantation for AL were included in the 'TBI group'. The 12 other patients who received chemotherapy alone (i.e. without TBI) were included in the 'no-TBI group'. Patients characteristics at the time of leukemia are summarized in Table 1 and more details on leukemia treatment are available in Supplementary Table B.

For all 24 patients, the diagnosis of MS was made during the LEA follow-up. The mean age at MS diagnosis was 29.0 ± 8.4 years in the TBI group vs 27.3 ± 6.5 years in the no-TBI group (NS). From MS diagnosis until inclusion in the present study, some patients changed their lifestyle and dietary habits. At the time of inclusion, nine patients still fulfilled three or more criteria for MS (4/12 in the no-TBI group and 5/12 in the TBI group).

Patients characteristics at inclusion, according to TBI treatment, are summarized in Table 2. The gender ratio (M/F) was respectively 1.4 in the no-TBI group and 0.5 in the TBI group. Mean age of patients at inclusion was 31.1 years in the no-TBI group and 32.9 years in the TBI group (NS). One male in the TBI group experienced a coronary event at the age of 30 years. Blood pressure was not different between groups.

Apolipoprotein CII and NEFA levels were increased in the TBI group compared to the no-TBI group (respectively 54 vs 33 mg/L, *P* = 0.05 and 0.6 vs 0.4 mmol/L, *P* = 0.05). Triglycerides and Apolipoprotein CIII levels tended to be higher in the TBI group without reaching statistical significance. At inclusion, there was no difference in the glucose parameters between the TBI and the no-TBI groups. Five patients were diagnosed with type-2 diabetes (three from the TBI group and two from the no-TBI group).

The hormonal status of each patient was evaluated at inclusion. Six patients from the TBI group and one from the no-TBI group had a history of hypothyroidism, which was corrected with thyroid hormone. No patient had a growth-hormone deficiency. Three patients in the TBI group presented with hypogonadism at inclusion (two men, one woman). Hormonal data according to group and gender are reported in Supplementary Table C.

Irradiated women are leaner with less intra-abdominal fat compared to no-TBI group

Among patients who developed MS, those who received TBI were significantly smaller and thinner than the

Table 1 Patients medical history.

	No-TBI (<i>n</i> = 12)	TBI (<i>n</i> = 12)	<i>P</i>
Characteristics of leukemia history			
Age at AL diagnosis (years, mean $\pm$ s.d.)	9.9 $\pm$ 4.3	6.8 $\pm$ 4.5	0.1
Leukemia type, <i>n</i>			
ALL	7	10	0.37
AML	5	2	
BMI at AL diagnosis (Z-score, mean $\pm$ s.d.)	0.7 $\pm$ 3.3	0.5 $\pm$ 1.0	0.31
BMI at AL diagnosis (kg/m ² , mean $\pm$ s.d.)	19 $\pm$ 8	17 $\pm$ 2	0.62
Time from AL diagnosis to last LEA visit (years, mean $\pm$ s.d.)	18.4 $\pm$ 8.7	23.8 $\pm$ 6.8	0.1

AL, acute leukemia; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; BMI, body mass index (weight/height²); TBI, total body irradiation

no-TBI group (15, 16) (Table 3). Mean BMI decreased by five points in the TBI group (25 vs 30 kg/m², *P*=0.06). This difference was more pronounced in women, known to develop more AT than men (mean BMI in TBI women at 26 vs 34 kg/m² in no-TBI women, *P*=0.03). After irradiation, waist and hip circumferences were ~10 cm and 20 cm lower in men (NS) and women (*P*=0.02), respectively. Gynoid and android fat masses, evaluated by DEXA were significantly decreased in women from the TBI group vs no-TBI (respectively, *P*=0.02 and *P*=0.045) (Table 3). Consistent with these data, there was a significant decrease in plasma-leptin levels in women from the TBI group (32 vs 53 ng/mL, *P*=0.045) (Table 3). Adiponectin concentrations were decreased in irradiated men (1.0 vs 2.5 μ g/mL, *P*=0.04).

In order to distinguish peripheral and intra-abdominal AT accumulation in MS patients, we performed abdominal

MRIs in the two groups. Twenty-two patients could have an MRI, but one patient presented with a contraindication and another refused the MRI. Intra-abdominal AT was significantly decreased in women within the TBI group (228 vs 373 cm², *P*=0.02) (Table 4). Other measures of AT (total AT surface as well as other specific AT sub-compartments: superficial compartmentalization: sSAT, that is, peripheral and deep intra-abdominal AT (dSAT and VAT) (29)) tended to decrease in both genders within the TBI group but without reaching the statistical significance.

Nutritional assessment and physical activity of the patients are described in Supplementary Table D. No difference was found between the two groups except for a decrease in resting energy expenditure in the TBI group in agreement with the thinner phenotype.

Liver steatosis increased in the group of irradiated patients

Since we have previously shown that irradiated patients have an increased insulin resistance despite lower body weight (15), we then studied liver steatosis, a characteristic feature of insulin resistance state and lipodystrophic syndromes. The mean liver fat content in the TBI group was almost two times greater (17 vs 9%, $P=0.008$) (Fig. 1).

When we studied independently women and men, hepatic triglyceride content was increased in both sex in the TBI group, but the difference did not reach statistical significance: respectively 17 vs 8% ($P=0.06$) in women and 16 vs 10% ($P=0.17$) in men. Accordingly, gamma GT enzymes were increased in the TBI compared to the no-TBI group (59 vs 40 IU/mL, $P=0.045$). Liver transaminases levels were unchanged between TBI and no-TBI groups (respectively 39 vs 28 IU/L, $P=0.18$ for AST,

Figure 1

Liver fat content. Hepatic triglyceride content was measured by proton magnetic resonance spectroscopy (^1H -MRS) using three voxels for each patient (left, right liver lobes and hepatic dome) for women, men and all patients in no-TBI group (white circles) and TBI group (black circles). ** $P < 0.01$.

and 46 vs 33 IU/L, $P=0.19$ for ALT). Two patients had regular alcohol consumption (respectively 6 and 8 g/day) and one patient had festive consumption in the no-TBI group; none in the TBI group reported drinking. The more pronounced liver steatosis was observed in the TBI group despite lower intra-abdominal fat. This discordance was illustrated by the ratio of the mean liver fat content related to intra-abdominal AT that was more than two times higher after TBI (0.08 vs 0.03, $P=0.02$).

Defect in fat storage and adipocyte differentiation in SAT of irradiated patients

We performed needle aspiration of sSCAT in 22 patients in order to analyze the gene expression of several proteins involved in AT homeostasis and for the study of pre-adipocyte differentiation in culture. Analysis of gene expression in sSAT revealed a decreased expression of genes involved in uptake and fatty acid biosynthesis, and in insulin sensitivity, in the TBI group: that is, 39% decrease for *SREBP-1c* gene expression ($P=0.01$) and 36% decrease for *CIDEA* gene expression ($P=0.004$). Adiponectin and *PPAR- γ* gene expression tended to decrease (18% decrease for adiponectin ($P=0.08$) and 18% decrease for *PPAR- γ* ($P=0.11$)). In addition, mRNA level of collagen 1a1 was 36% lower in the TBI group ($P=0.03$). No significant difference was found for the AT inflammatory parameters (Fig. 2).

Pre-adipocytes number in sSAT evaluated by flow cytometry and expressed in cell number/g of AT did not differ between the two groups of patients (Fig. 3A). The adipogenic differentiation was then assessed by counting mature adipocytes and performing RT-qPCR on cell culture

after 7 days of differentiation. As shown in Fig. 3B and C, the number of mature adipocytes tended to decrease in the TBI group (261 ± 197 vs 173 ± 89 adipocytes/ mm^3 in no-TBI and TBI groups respectively, NS). As expected, adipocyte differentiation induced increased expression of *PPAR- γ* , *aP2*, leptin, *LPL* and *GPDH* in both groups. However, the induced expression of most of these genes was 2–4 times lower in differentiated cells belonging to the TBI group compared to no-TBI ($P=0.04$ for all), indicating that the extent of adipocyte differentiation was reduced following TBI (Fig. 3D).

Discussion

To our knowledge, this is the first study which evaluates the impact of irradiation on AT in survivors of childhood AL. We have shown that patients who received TBI during childhood and who developed MS in adulthood have nearly two times more liver fat than AL survivors who developed MS but did not received irradiation. These differences were observed although irradiated patients had less body fat. This lower AT mass development is supported at the molecular level by lower gene expression of proteins involved in fatty acid metabolism and fat storage associated to a profound alteration of pre-adipocyte differentiation.

Thus, we first have confirmed that patients who underwent irradiation were more prone to metabolic abnormalities despite the lower BMI and lower waist circumference (16). However, waist circumference, which is correlated with visceral AT in the general population, is one of the five criteria used to define MS in the classical NCEP-ATP-III definition (4). Thus, in this specific population of irradiated patients, the measurement of waist circumference is not accurate when defining MS. These data highlight the need for clinicians to search for metabolic disorders in all patients who had TBI during childhood, even when the patient's BMI and waist circumference are within normal range.

Liver fat is strongly correlated with insulin resistance, type-2 diabetes and CVD (30). An important result of this study is the nearly two-fold increase in liver fat found in the TBI group. Other studies have also reported an increase in liver steatosis in survivors of pediatric cancers after irradiation (12, 31, 32). Epidemiological studies have consistently demonstrated a strong association between VAT and hepatic triglyceride content (30). However, we found a higher rate of liver steatosis after TBI, despite lower abdominal AT (significantly decreased

Figure 2

Impact of TBI on total subcutaneous adipose tissue. Gene expression levels involved in inflammation, fibrosis and lipogenesis between the no-TBI group (white bars) ($n = 10$) and the TBI group (black bars) ($n = 10$). ANGPTL2, angiopoietin like 2; CD, cluster of differentiation; CIDEA, cell death-inducing DNA fragmentation factor alpha-like effector A; COL, collagen; DGAT2, diacylglycerol O-acyltransferase 2; HIF, hypoxia inducible factor; IL, interleukin; MCP1, monocyte chemoattractant protein-1; MMP, matrix metalloproteinase; PPAR, peroxisome proliferator-activated receptor; SREBP1c, sterol regulatory element-binding protein 1; TBI, total body irradiation; TIMP, tissue inhibitor of metalloproteinases; TGF, transforming growth factor.

in women). In accordance with our results, a recent study on nonhuman primates showed a significant reduction in VAT associated with a higher rate of liver steatosis after radiation exposure (33). We hypothesize that irradiation could alter the capacity of visceral adipocytes to undergo hyperplasia and/or differentiation, thus explaining

this particular feature of high liver fat despite low VAT. Numerous recent studies have demonstrated that ectopic fat deposits are secondary to the relative inability of SAT to properly store energy and expand when there is a positive energy balance (34). In lipodystrophic syndromes, impairment in the ability of SAT to properly

Figure 3

Differentiation of pre-adipocytes in culture. (A) Flow cytometry was performed to compare the number of pre-adipocyte cells/g of total SAT in the stromal-vascular fraction from the no-TBI group (black circles) ($n = 6$) and the TBI group (black squares) ($n = 6$). (B) Picture of pre-adipocytes culture after 7 days of differentiation in no-TBI group (up) and TBI group (down). (C) Comparison of the number of adipocytes/mm³ after 7 days of differentiation. (D) Expression levels of genes involved in adipocyte differentiation in patients who received TBI ($n = 8$) or not ($n = 7$). Cultured pre-adipocytes were studied before (D0) (white bars) and at 7 days (D7) (gray bars) of differentiation. $*P < 0.05$. aP2, adipocyte protein 2; GPDH, glycerol-3-phosphate dehydrogenase; LPL, lipoprotein lipase; PPAR, peroxisome proliferator-activated receptor.

expand leads to ectopic fat accumulation with insulin resistance and to fatty liver (18). Accordingly, in a recent 4-year longitudinal study, the authors demonstrated that large areas of SAT at baseline seemed to be protective against NAFLD (nonalcoholic fatty liver disease) (35). Similarly, we observed a significantly higher rate of liver steatosis associated with a lower BMI, and a trend toward decreased TAT and SAT after TBI in patients who had been irradiated. All these observations are in favor of an inability of AT to properly expand after irradiation. It is important to note that one patient in the TBI group was diagnosed with hepatic fibrosis during the follow-up period, as a consequence of liver steatosis (diagnosed with a fibroscan). We demonstrate here that the screening for metabolic disorders and NAFLD in patients who received TBI in childhood is essential for their long time follow-up.

When we studied the functional aspects of SAT in the long-term AL survivors after irradiation, we found a significantly reduced gene expression of *CIDEA* and *SREBP1c*, which are involved in the uptake and biosynthesis of fatty acids and play an important role in metabolic homeostasis. Indeed *CIDEA* level in white AT is positively correlated with expandability of SAT, insulin sensitivity and healthy obesity in mice (36). *SREBP1c* is an important pro-adipogenic transcription factor that directly regulates the expression of several key genes in lipid metabolism and also regulates adipogenesis (37). The reduced gene expression of *CIDEA* and *SREBP1c* in SAT observed after irradiation could explain the incapacity of SAT to properly expand, leading to ectopic fat accumulation. Moreover, our results show that the differentiation capacity of adipocyte precursor cells was altered in the SAT of irradiated patients, with a clear reduction in the expression levels of several key genes involved in pre-adipocyte differentiation and lipid accumulation. This lower extent of adipose differentiation following TBI was consistent with a slightly reduced adipocyte number in culture in the TBI group compared to the no-TBI one. These results were also consistent with the significant decrease in the proliferation and differentiation capacity of pre-adipocytes following irradiation in mice (19). It would have been informative to measure adipocyte size in these patients. Unfortunately, the AT samples we obtained by needle aspiration were too disrupted to allow a proper histological analysis. This minimally invasive technique was used instead of the biopsy for ethical reasons because patients have usually already undergone many invasive treatments.

We did not find any difference between groups regarding local inflammation in SAT. This is in agreement

with the fact that liver steatosis and insulin resistance are not related to AT inflammation in lipodystrophic syndromes (38). Altogether, these results support the direct effect of irradiation on AT, leading to alteration in pre-adipocyte differentiation and AT fat storage, thus causing increased TG accumulation within the liver.

Our data on irradiated patients were particularly clear for women known to develop more AT than men. Indeed, the differences in BMI and waist circumference between the two groups were more pronounced for women and a decrease in fat mass and intra-abdominal fat was only observed in women. Other studies have also reported that girls are more prone to having a lower BMI after irradiation (32, 39). Further studies are needed to explore the reasons for a higher susceptibility to irradiation in women.

Several other factors are involved in the greater risk of developing MS and CVD, specifically after irradiation. TBI is associated with a high risk of developing endocrine disorders at the time of treatment and later on: i.e., growth-hormone deficiency, hypothyroidism and gonadic dysfunction (39). In the present study, no growth-hormone deficiency, which is frequently associated with insulin resistance, was diagnosed at inclusion. Despite being within the normal range, thyroid levels did statistically differ between the two groups; however, this difference is unlikely to have caused insulin resistance. Three patients in the TBI group presented with hypogonadism at inclusion. Hypogonadism could lead to insulin resistance but few data show a link between low levels of testosterone and liver steatosis (40). Regarding other risk factors for MS, our previous study (41) did not find any correlation between the use of steroid for AL treatment and MS in irradiated patients. An increased BMI at the time of AL diagnosis has been proposed as a risk factor for developing MS in TBI patients (6), but we did not find any difference in the BMIs of the two groups (at the time of AL).

Conclusion

In conclusion, long-term survivors of childhood AL who received TBI treatment may present features of lipodystrophy, even decades later. Thus, long-term appropriate follow-up is necessary for these patients. NAFLD should be detected in all patients after TBI. Clinicians should continue to provide screening and preventive care for MS and CVD to irradiated patients, even though they have a normal waist circumference and BMI.
