Abstract

Background: The management of adrenal incidentaloma is still a challenge with respect to determining its functionality (hormone secretion) and malignancy. In this light, we performed $^{18}$F-FDG PET/CT scan to assess the SUV$_{\text{max}}$ values in different adrenal masses including Cushing syndrome, pheochromocytoma, primary hyperaldosteronism and non-functional adrenal adenomas.

Methods: Total 109 (73 F, 36 M) patients with adrenal mass (incidentaloma), mean age of 53.3 ± 10.2 years (range, 24–70) were screened by $^{18}$F-FDG PET/CT. Data of $^{18}$F-FDG PET/CT imaging of the patients were assessed by the same specialist. Adrenal masses were identified according to the calculated standardized uptake values (SUVs). Clinical examination, 24-h urine cortisol, catecholamine metabolites, 1-mg dexamethasone suppression test, aldosterone/renin ratio and serum electrolytes were analyzed.

Results: Based on the clinical and hormonal evaluations, there were 100 patients with non-functional adrenal mass, four with cortisol-secreting, four with pheochromocytomas and one with aldosterone-secreting adenoma. Mean adrenal mass diameter of 109 patients was 2.1 ± 4.3 (range, 1–6.5 cm). The $^{18}$F-FDG PET/CT imaging of the patients revealed that lower SUV$_{\text{max}}$ values were found in non-functional adrenal masses (SUV$_{\text{max}}$ 3.2) when compared to the functional adrenal masses including four with cortisol-secreting adenoma (SUV$_{\text{max}}$ 10.1); four with pheochromocytoma (SUV$_{\text{max}}$ 8.7) and one with aldosterone-secreting adenomas (SUV$_{\text{max}}$ 3.30). Cortisol-secreting (Cushing syndrome) adrenal masses showed the highest SUV$_{\text{max}}$ value (10.1), and a cut-off SUV$_{\text{max}}$ of 4.135 was found with an 84.6% sensitivity and 75.6% specificity cortisol-secreting adrenal adenoma.

Conclusions: Consistent with the similar studies, non-functional adrenal adenomas typically do not show increased FDG uptake and a certain form of functional adenoma could present various FDG uptake in FDG PET/CT. Especially functional adrenal adenomas (cortisol secreting was the highest) showed increased FDG uptake in comparison to the non-functional adrenal masses. Therefore, setting a specific SUV$_{\text{max}}$ value in the differentiation of malignant adrenal lesion from the benign one is risky and further studies, including a high number of functional adrenal mass are needed.

Key Words

- $^{18}$F-FDG PET-CT
- Cushing syndrome(s)
- pheochromocytoma(s)
- non-functional adrenal adenomas
Introduction

Since the early 1980s, the prevalence of adrenal masses have been increasing due to the frequent use of radiological imaging such as magnetic resonance imaging (MRI), computerized tomography (CT) in clinical practice. The prevalence of adrenal incidentalomas detected by abdominal CT scan varies between 2.5 and 4% in adult populations. The management of adrenal incidentalomas depends on the lesion's being benign or malignant and any adrenal hormone secretion related with the Cushing syndrome, primary aldosteronism and pheochromocytoma. Based on the obtained findings, functional adrenal masses and malignant potential tumors are operated on, whereas those with non-functional and benign characteristic of radiological evaluation are only followed up to 5 years (1, 2). According to the current endocrine and surgical guideline (3), every patient elaborately adhered to the endocrine and imaging procedures. Despite performing a cascade of the tests and procedures, identification of some lesions still remains uncertain (4, 5). Especially, bilateral adrenal masses are still a clinical dilemma for clinicians. In the initial diagnosis, CT or MRI are common preferable imaging techniques for adrenal masses, but CT and/or MRI do not separate the functional adenomas from the non-functional adenomas.

$^{18}$F-FDG positron emission CT was originally developed to evaluate benign and malignant lesions. However, there were limited studies on the usage in determining the functional status of adrenal incidentalomas. In certain studies, it was reported that $^{18}$F-FDG PET CT could help in the differentiation of adrenal masses with and without hormone secretion (6, 7).

In this study, we aimed at determining whether $^{18}$F-FDG PET/CT scanning of adrenal mass could identify the functional status of the adrenal masses. We also made a comparison between the pathological diagnosis and $^{18}$F-FDG PET/CT imaging of functional adrenal masses which mimicked malignant lesion.

Patients and methods

Study populations

During a 24-month period, 109 patients (73 females, 36 males) with adrenal mass who were referred to the university hospital for further investigation by $^{18}$F-FDG PET/CT imaging were included. All adrenal masses were incidentally detected on CT or MRI for other reasons. Past medical history, comorbid disorders, drug administration and family history for any genetic disease were questioned.

In the physical examination, body mass index (BMI), blood pressure measurements and routine systematic examination were performed. Especially, attention on stigmas of Cushing syndrome and high blood pressure for primary aldosteronism and pheochromocytoma were taken into consideration.

All patients were screened for hyperaldosteronism, hypercortisolism and pheochromocytoma. Plasma renin/aldosterone ratios, plasma normetanephrine, metanephrines and urinary free cortisol (UFC) were also studied. Autonomous cortisol secretion was described as serum cortisol >1.8 µg/dL following 1 mg of overnight dexamethasone suppression test or 2 days of low-dose dexamethasone suppression test plus the following additional measurements; 24-h urinary free cortisol excretion (UFC), suppressed serum adrenocorticotropic hormone (ACTH) levels (<10IU/mL) and elevated midnight serum or salivary cortisol values (3).

All patients were evaluated by the same multidisciplinary expert team as similar to the international studies and the following criteria were considered (3):

1. Those that had radiological imaging of adrenal lesions were reported as suspicious for malignancy.
2. Those who had evidences of hormone hypersecretion (Cushing syndrome, primary aldosteronism, pheochromocytoma),
3. Those who had hormone hypersecretion with comorbid disorders including diabetes mellitus, hypertension, osteoporosis, obesity, and
4. Those with adrenal mass diameter above 6 cm or with an increase in the diameter on the 6-month follow-up imaging were taken to adrenal surgery.

Post-operative histopathological diagnosis of the specimens was studied by the same experienced pathologist. Weiss criteria (8) were used for adrenocortical adenomas and PASS criteria (Pheochromocytoma of the Adrenal Gland Scaled Score) (9) for pheochromocytoma.

Inclusion criteria of the subjects were as follows: patients with non-functional or functional adrenal masses (i.e. CS, primary aldosteronism, pheochromocytoma). Exclusion criteria were history of malignancy, any chronic drug use such as cortisol and its analogs.

DHEAS, ACTH and cortisol values were analyzed by using the PCR method, the enzymatic-labeled chemiluminescent immunometric assay method, and chemiluminescence (Beckman DXI 800 auto analyzer; Beckman Coulter Diagnostics), respectively. PRA and PA levels were measured using the radioimmunoassay
method. The high performance liquid chromatography (HPLC) method was used to analyze urine cortisol and metanephrine values.

PET-CT imaging: patients were analyzed by a consensus of experienced nuclear medicine physicians who were blind for the patient data, except for the adrenal side (left or right) of the mass. Adrenal mass was objectively analyzed by the measurement of the calculated standardized uptake value (SUV). The activity of the adrenal mass was obtained by drawing a region of interest (ROI) that encompasses the central two-thirds of the mass if relatively homogeneous or the most uniform area if the mass was heterogeneous. In this study, SUV_{max} cut-off value for adrenal malignant lesions was considered as 4.04 as previously reported by Blake et al. (10).

The study was approved by Cukurova University Ethical Committee in 2017. Written informed consent was obtained from all patients.

Statistical analysis

Data distribution was tested by the Shapiro–Wilk test. Mean and standard deviations were presented for normal distributed variables; for non-normal distributed variables, median and quartile statistics were given. Pearson correlation coefficient was calculated to examine the linear relationship between two continuous variables. Student t and one-way ANOVA tests were performed to compare the mean differences between the subgroups. To assess the performance of the diagnostic tests, ROC curves were performed, sensitivity, specificity, positive predictive and negative predictive values were calculated.

Results

Mean age of the patients was 53.3 ± 10.0 years (range 24–70 years). Mean adrenal mass diameter of the subjects was 2.1 ± 4.3 cm (range 1.0–8.0). Mean adrenal mass diameters of nine functional adenomas were as follows: hypercortisolemia (Cushing syndrome) 2.5 ± 1.6 cm (range, 1.7–4.1 cm); pheochromocytoma 4.1 ± 2.3 cm (range, 2–6.4) and aldosterone-secreting adenoma 1 cm. There were four patients with non-functional and adrenal mass diameter of ≥6 cm (range, 6–8). Of four patients presented with cortisol hypersecretion, two were operated due to the evidences of Cushing syndrome-related comorbid disorders such as type 2 diabetes and obesity. Of 109 patients, 65 (59.6%) had left-sided adrenal mass and the remaining 44 (40.4%) had right-sided adrenal mass.

Post-operative diagnosis

In the post-operative pathological diagnosis of the 13 patients who underwent surgery, 11 subjects were diagnosed as having adrenocortical adenoma (Weiss criteria <4) and two as adrenocortical carcinoma. One of the two patients with adrenocortical carcinoma was diagnosed with pheochromocytoma (Pass criteria >4, SUV_{max} 8.2). The other patient had a non-secretory adrenocortical carcinoma (Weiss criteria >4, SUV_{max} 6.9) (Fig. 1D). When we grouped the pathological diagnosis of the patients according to the functional status of adrenal mass, diagnosis of the patients with Cushing syndrome was adrenal adenoma (Weiss criteria <4), three patients with pheochromocytoma also had adenoma (Weiss criteria <4) and the remaining one patient had carcinoma (Weiss criteria >4). The pathological diagnosis of the patients is shown in Table 1.

18F-FDG PET/CT imaging

The results of 18F-FDG PET/CT imaging of the patients were that four patients with hypercortisolemia (CS and autonomous cortisol secretion) showed higher SUV_{max} values of 10.1 ± 3.2 (range, 4.17–13.66) compared to that of the 100 patients with non-functioning adenomas (SUV_{max} of 3.2 ± 1.6) (range, 1.5–4.9) (P<0.001) (Fig. 1A, B and C).

A cut-off SUV_{max} of 4.135 was found as an identifying value for a cortisol-secreting adrenal mass with a sensitivity of 84.6% and specificity of 75.6% (Fig. 2).

Four patients with pheochromocytoma showed moderate-to-high SUV_{max} values (8.7 ± 2.7) compared to the patients with non-functioning adenomas (P<0.005) (Fig. 1B, C and Table 1). Of 109 patients, 13 (11.9%) were operated due to functional adrenal mass (n=9) and malignancy risk (n=4) according to the CT findings revealing a tumor size of ≥6 cm. The patients who were operated due to functionality and/or mass size of ≥6 cm (n=13, 11.9%) revealed higher SUV_{max} value than the patients without an operation (9.06 ± 7.01 vs 3.23 ± 1.65, P<0.001). There was no statistically significant correlation between mass size and SUV_{max} value (P=0.280).

To determine whether background metabolic activity could be some false-positives among adrenocortical adenomas, we calculated specific criteria called as adrenal to liver SUV_{max} ratio (uptake of 18F-FDG adrenal/uptake of 18F-FDG liver ratio).

For all patients with adrenal masses, adrenal-to-liver SUV_{max} ratio was calculated as 0.83 ± 0.72. For patients with
carcinoma, adrenal-to-liver SUV\textsubscript{max} ratio was calculated as 2.74±1.2. For patients with hypercortisolemia, adrenal-to-liver SUV\textsubscript{max} ratio was 4.13±5.83; for patients with pheochromocytoma, it was 1.76±0.86 and for patients with non-functional it was 0.79±0.38.

**Discussion**

In the management of adrenal masses, CT with/without contrast-enhanced and chemical shift magnetic resonance imaging (MRI) has been used as the initial imaging protocols (11, 12, 13, 14). Attenuation characteristics by Hounsfield Unit (HU) of adrenal masses are generally accepted to differentiate adenomas from non-adenomas masses. Nevertheless, CT and MRI scanning cannot distinguish between adenomas with and without hormone secretion (15, 16, 17). Hence, in addition to the imaging findings, endocrinologic assessment of the adrenal masses is necessary as well as the issue of malignancy.

\(^{18}\)F-FDG PET/CT is a nuclear medicine method and based on glucose and deoxyglucose uptake by cancer cells. In this technique, standard uptake value (SUV) has been commonly used as a measurement index (18, 19). Until now, nuclear scintigraphy (iodocholesteoral or \(^{123}\)I/\(^{131}\)I-labeled metaiodobenzylguanidine) have been used to determine the functional hormone secretions of adrenal masses (20). However, in some recent studies using

PET/CT showing a 1.4×1.7 cm left-cortisol-secreting adenoma with SUV\textsubscript{max} 11.38. (B) Coronal and axial fused \(^{18}\)F-FDG PET/CT images of the patient 2 adrenal glands which were diagnosed pheochromocytoma. PET/CT showing a 3.0×2.1 cm right-pheochromocytoma with SUV\textsubscript{max} 7.86. (C) Coronal and axial fused \(^{18}\)F-FDG PET/CT images of the patient 3 adrenal glands which were diagnosed non-functional adrenal adenoma. PET/CT showing a 52×50 cm non-functional adenoma with SUV\textsubscript{max} 4.56. (D) Adenoma cells have abundant intracytoplasmic granular lipofuscin pigment with eosinophilic cytoplasm (patient 1, left side, H-E ×400). The cells of pheochromocytoma have a finely granular, basophilic cytoplasm with round-to-oval nuclei (patient 2, middle part, H-E ×200). The cells of the neoplasm have diffuse pattern with lack of clear cytoplasm (patient 3, right side, H-E ×200).
18F-FDG uptake in the adrenal masses, increased uptake was reported in functional adrenal masses (21, 22, 23, 24, 25). Many factors may affect SUV measurements such as weight or blood glucose level, duration of uptake period or the type of ROI. Due to these variables, some authors prefer to use adrenal to liver SUV\textsubscript{max} instead of only adrenal SUV\textsubscript{max} value. And studies reported that most of the adrenal adenomas had FDG uptake (mean ratio 0.66) less than the liver (26, 27, 28, 29). In 2009, Groussin et al. (30) studied this method in subjects without a previous cancer history to predict the malignancy of adrenal masses. In this study, a cut-off value above 1.45 for adrenal to liver SUV\textsubscript{max} ratio was suggested in favor of adrenal adenoma. Nearly all of these studies were on whether the adrenal mass was malign or non-malign. In this study, adrenal-to-liver ratio of patients with carcinoma was calculated as 2.74 ± 1.2. While adrenal-to-liver SUV\textsubscript{max} value of patients (n = 96) with non-functional adrenal mass was found as 0.79 ± 0.38; adrenal-to-liver SUV\textsubscript{max} value of patients with hypercortisolemia was detected as 4.13 ± 5.83. Adrenal-to-liver SUV\textsubscript{max} ratio in patients with hypercortisolemia was a false positive compared to patients with carcinoma, but there was not any correlation between malignant masses and secreting but non-malignant tumors because of sample size of the patients.

With respect to the functional adrenal mass, Patel et al. (31) reported that cortisol-secreting adenomas showed higher SUV\textsubscript{max} values (5.9), not only compared to non-functional adrenal adenomas (SUV\textsubscript{max} 4.2) but also to aldosterone-secreting adenomas (SUV\textsubscript{max} 3.3) (P<0.007). Some of the similar studies also supported these findings (22, 23, 24, 25, 32). Consistent with these studies, we found higher SUV\textsubscript{max} (10.1 ±3.2) in patients with cortisol-secreting adrenal adenoma compared to patients with non-functional adrenal adenomas (SUV\textsubscript{max} 3.2 ±1.6) (P<0.001). In 2011, Vassiliadi and colleagues (33) reported that patients with adrenal masses who had an odds ratio of 5.50 predicted the autonomous cortisol secretion. In another study, it was also reported an increased 18F-FDG uptake in patients with cortisol-hypersecreting benign adrenal adenoma (34). Hypercortisolemia was suggested as an underlying mechanisms for high SUV\textsubscript{max} values in cortisol-secreting adrenal adenomas due to an increased glucose metabolism (21, 31). Similarly, in our study in patients with hypercortisolemia (Cushing syndrome and subclinical cortisol secretion), an increased 18F-FDG uptake was found compared to other patients. Unfortunately, we had a limited case of cortisol-secreting adrenal adenoma.

We used the patients with non-functional nonoperated adrenal mass as control to compare the patients with secreting adrenal masses in the Student t-test. Bold indicates statistical significance.

\(^a\)Weiss criteria <4 criteria; \(^b\)Pass Criteria <4 criteria; \(^c\)Pass Criteria >4 criteria; \(^d\)Weiss criteria >4 criteria.

\(N\) means the number of patients, \(SUV\textsubscript{max}\) represents SUV\textsubscript{max} value. Patients with share the same superscript in the same column were compared using Student t-test. Values that are statistically significant are shown in bold.
Efficacy of PET-CT in adrenal mass

F-FDG PET CT screening may be helpful in searching for functional characteristics. In addition, we need to know the value of the non-functional adrenal masses. There is a need for further more extensive studies to report conclusive results.

Limitations

Because our study was a pilot study, the sample size was relatively small. Lack of a healthy-control subject group and patients with functional adrenal mass to compare with patients with non-functional adrenal incidentaloma may be thought as the deficiency of the study. Besides, our study was mainly focused on the characteristics and SUVmax Value of the non-functional adrenal masses. There is a need for further more extensive studies to report conclusive results.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding

This work did not receive any specific grant from any funding agency in the public, commercial, or not-for-profit sector.
